Abstract—The use of mobile sensors is of great relevance for a number of strategic applications devoted to monitoring critical areas where sensors can not be deployed manually. In these networks, each sensor adapts its position on the basis of a local evaluation of the coverage efficiency, thus permitting an autonomous deployment.

Several algorithms have been proposed to deploy mobile sensors over the area of interest. The applicability of these approaches largely depends on a proper formalization of rigorous rules to coordinate sensor movements, solve local conflicts and manage possible failures of communications and devices.

In this paper we introduce P&P, a communication protocol that permits a correct and efficient coordination of sensor movements in agreement with the PUSH&PULL algorithm. We deeply investigate and solve the problems that may occur when coordinating asynchronous local decisions in the presence of an unreliable transmission medium and possibly faulty devices such as in the typical working scenario of mobile sensor networks.

Simulation results show the performance of our protocol under a range of operative settings, including conflict situations, irregularly shaped target areas, and node failures.

I. INTRODUCTION

The research in the field of mobile wireless sensor networks is motivated by the need to monitor critical scenarios such as wild fires, disaster areas, toxic regions or battlefields, where static sensor deployment cannot be performed manually.

In these typical working situations, sensors may be dropped from an aircraft or sent from a safe location. In these cases the initial deployment over the Area of Interest (AoI) is neither complete nor uniform as would be necessary to enhance the sensing capabilities and extend the lifetime of the network. Mobile sensors can dynamically adjust their position to improve coverage with respect to their initial deployment. Sensor movements should therefore be coordinated according to a distributed deployment algorithm.

Out of the solutions proposed in the literature so far for mobile sensor deployment, those described in [1], [2], [3], [4] are based on the virtual force approach which models the interactions among sensors as a combination of attractive and repulsive forces. Other approaches are inspired by the physics of fluids and gases such as [5] and [6]. Another methodology is based on the construction of Voronoi diagrams [7], [8].

According to this proposal, each sensor iteratively calculates its own Voronoi polygon, determines the existence of coverage holes and moves to a better position if necessary. The solutions proposed in [9] and [10] provide instead density driven actions to uniformly distribute sensors according to a regular grid pattern.

The applicability of these deployment algorithms largely depends on the proper formalization of rigorous rules to coordinate sensor movements, solve local conflicts and manage possible failures of communications and devices.

Previous proposals only focus on the design of distributed algorithms for the adaptive deployment of mobile sensors, aiming at covering the area of interest according to given efficiency objectives, in particular coverage completeness and uniformity and low energy consumption. Seldom do previous works enter the details of the communication protocol necessary to enable the application of the proposed algorithms.

The main contribution of this paper is a communication protocol that defines the rules to deploy mobile sensors according to the PUSH & PULL algorithm proposed in [10]. This algorithm is based on the autonomic computing paradigm. It completely delegates to the single sensors every decision regarding movements and action coordination. This way self-organization emerges without the need of external coordination or human intervention as the sensors adapt their position on the basis of their local view of the surrounding scenario.

Given the absence of a centralized coordination unit, and the lack of synchronization, sensors have a primary role in the realization of the algorithm actions. Therefore, the design of the related coordination protocol is particularly challenging.

Indeed, under the execution of the PUSH & PULL algorithm, several types of conflicts may occur as several sensors often compete to cover the same position. Sensors should be capable to solve such conflicts by means of only local interactions. We deeply investigate and solve the problems that may occur when coordinating asynchronous local decisions in the presence of an unreliable transmission medium and possibly faulty devices that characterizes the typical working scenario of mobile sensor networks.

The proposed protocol works in respect of the algorithm

goals, permitting the realization of a complete and uniform stable coverage, with low energy consumption. Simulation results show the performance of our protocol under a range of operative settings, including conflict situations, irregularly shaped target areas, and node failures.

II. BRIEF DESCRIPTION OF THE PUSH & PULL ALGORITHM

PUSH & PULL is a completely distributed algorithm [10] for the realization of an autonomous deployment of mobile sensors. According to this algorithm sensors perform a complete coverage of the AoI by means of a hexagonal tiling. Initially, several tiling portions are created concurrently and every sensor not yet involved in the creation of a tiling portion gives start to a portion of its own in an instant randomly selected over a given time interval. In order to make the exposition clearer, we outline the algorithm, before giving details on the implementing protocol.

Let V be a set of equal sensors endowed with location determination, boolean sensing and isotropic communication capabilities. Sensors are kept in active mode for all the deployment phase. The deployment consists in realizing a hexagonal grid with side length equal to the *sensing radius* R_s . This setting guarantees both coverage and connectivity when $R_{tx} \geq \sqrt{3}R_s$. A sensor which is deployed at the center of a hexagonal tile is called *snapped*. $Hex(x)$ is the hexagonal region whose center is covered by the snapped sensor x . All the other sensors lying in $Hex(x)$ are called *slaves* of x and compose the set $S(x)$. All sensors that are neither snapped nor slaves are called *free*. The set composed by the free sensors located in radio proximity to p and by its slaves is denoted by $L(p)$. In the following, s_{init} denotes any of the starter sensors.

The four main activities of the algorithm, *Snap*, *Push*, *Pull*, *Merge*, are executed in an interleaved manner as described in the following paragraphs.

Snap activity. At the beginning, each sensor may act as starter of a snap activity from its initial location at an instant randomly chosen over a given time interval. Sensor s_{init} elects its position as the center of the first hexagon of its tiling portion and changes its status to snapped.

Any just snapped sensor p performs a *neighbor discovery*, that allows it to gather information regarding the sensors belonging to $L(p)$. Among these, p selects at most six sensors to make them snap to the center of adjacent hexagons.

A snapped sensor leads the snapping of as many slaves as possible. If all the hexagons adjacent to $Hex(p)$ have been covered, p stops any further snapping. If, after the completion of the snap action, the snapped sensor has still some slaves in its hexagon, it gives start to the push activity. Otherwise, if some hexagons are left uncovered because no more sensors in $L(p)$ are available, p starts the pull activity.

Such deployed sensors, in their turn, give start to an analogous selection and snap activity, thus expanding the boundary of the current portion. This process goes on until no other snaps are possible, because either the whole AoI is covered,

or all sensors located at boundary tiles do not have any un-snapped sensor to snap.

Push activity. Snapped sensors, after the completion of their snapping activity, may still be surrounded by un-snapped sensors located inside their hexagon. In this case, they proactively push such un-snapped sensors towards lower density areas located within their transmission range.

Given two snapped sensors p and q located in radio proximity from each other, p may offer one of its slaves to q and push it inside the hexagon of q if $|S(p)| \geq |S(q)| + 1$.

The push activity is allowed in the only directions that verify the *Moving Condition* according to which the movements of sensors from $Hex(p)$ to $Hex(q)$ are restricted to the only cases in which:

$$\{|S(p)| > |S(q)| + 1\} \vee \{|S(p)| = |S(q)| + 1 \wedge ord(p) > ord(q)\}.$$

where $ord(\cdot)$ is a function initially set to the unique identity code of the sensor radio device.

In order to avoid inconsistencies the snapped sensors involved in a push activity always advertise their neighborhood of the changes in the number of slaves as if the ongoing movements were already concluded.

Pull activity. Snapped sensors may detect a coverage hole adjacent to their hexagon and not have available sensors to snap. In this case, they send hole trigger messages, so reactively attracting un-snapped sensors and making them fill the hole.

Namely, let p be a snapped node detecting a hole in an adjacent hexagon, with $L(p) = \emptyset$. If p has not the possibility to receive any slaves from its neighbor hexagons, i.e. the Moving Condition is not verified for any of them, then it activates the following trigger mechanism.

Sensor p temporarily alters the value of its ord function to 0 and notifies its neighbors of this change by means of a *trigger notification message*. This could be sufficient to make the Moving Condition true with at least a snapped neighbor, so p waits until either a new slave comes into its hexagon or a timeout expires. If a new slave enters in $Hex(p)$, p sets back its ord value and snaps the new sensor, filling the hole. If the timeout expires and the hole has not been covered yet, the trigger mechanism is extended by forwarding the trigger message to the adjacent hexagons of p , whose snapped sensors set their ord value to 1. This mechanism is iterated by p over snapped sensors at larger and larger distance in the tiling until an available slave is attracted and the hole is covered.

This way, each snapped sensor involved in the trigger notification mechanism sets its ord value proportional to the distance from p . All the timeouts related to each new forwarding are set proportionally to the distance reached by the trigger mechanism. At the expiration of the trigger timeout, each involved node sets back its ord to the original value.

Observe that, the detection of several holes may cause the same sensor to receive more than one trigger message that it stores in a pre-emptive priority queue, giving precedence to the messages related to the closest hole.

Tiling merge activity. The possibility that many sensors act as starters may temporarily lead to the creation of several tiling portions with different orientations.

Algorithm PUSH & PULL provides a mechanism to merge all these tiling portions into a unique regular and uniformly oriented tiling. When the boundaries of two tiling portions come in radio proximity with each other, the one which was started first absorbs the other by making its snapped sensors move into more appropriate snapping positions.

The combination of the described activities expands the tiling and, at the same time, does its best to uniformly distribute redundant sensors over the tiled area, avoiding oscillations.

III. THE SENSOR COORDINATION PROTOCOL P&P

The implementation of the PUSH & PULL algorithm requires the definition of a protocol for the local coordination of the sensor activities.

The coordination protocol provides the rules to solve contentions that may happen in several cases. For example, two or more snapped sensors can decide to issue a snap command to different sensors towards the same hexagon tile or the same low density hexagon can be selected by several snapped sensors as candidate for receiving redundant slaves. These contentions are solved by properly scheduling actions according to message time-stamps and by advertising related decisions as soon as they are made. The P&P protocol is designed to minimize energy consumption entailing a small number of message exchanges, which is possible because the algorithm decisions are only based on a small amount of local information. Furthermore, we assume that P&P works over a communication protocol stack which handles possible transmission errors and message losses by means of timeout and retransmission mechanisms. Therefore the treatment of occasional message losses at the underlying protocol level implies the occurrence of delays in the corresponding messages at the P&P level that are dealt by P&P with proper timeout mechanisms.

Before we enter the details of the protocol we introduce some definitions. Remember that sensors may be in one of the following state: *snapped*, *free* or *slave*.

The *real cardinality* of a snapped sensor p is the number of slave sensors actually located inside $Hex(p)$, that p can utilize to perform the snap, push and pull actions. The *virtual cardinality* of p differs from the previous one as it is calculated considering all the ongoing snap, push, pull actions as if they were already concluded. The set $VP(p)$ of vacant positions detected by sensor p contains the centers of hexagons adjacent to $Hex(p)$ that are not yet occupied by any snapped sensor.

Table I contains a summary of the message types used by protocol P&P.

IV. P&P: SNAP ACTIVITY

In order to describe the snap activity, we need to distinguish three cases, according to the role of the involved sensor. Indeed the actions undertaken by the starter sensors, the

already snapped sensors and the sensors being snapped, are substantially different.

A. Starter sensor behavior

At the beginning, any sensor p may give start to the creation of a tile portion by snapping itself to its present position in an instant of time $t_{start}(p)$ randomly selected over a time interval of length R_{tx}/v , where v is the sensor movement speed. If at the instant $t_{start}(p)$, sensor p has not yet received any message, it elects its position as the center of the first hexagon and establish the orientation of its tile portion. At this point p executes the snap actions under the role of snapped sensor, as described in the following paragraph.

B. Snapped sensor behavior

1) *Neighbor Discovery*: A snapped sensor p broadcasts a IAS (I Am Snapped) message to perform a neighbor discovery. Such message contains the ID of the sender snapped sensor, its geographic coordinates and the timestamp of the starter action. All sensors located in radio proximity to p (with the exception of those slaves located in different hexagons) reply to its IAS, with a message containing role dependent information: the snapped sensors reply with an InfoSnapped message, while the slave and the free sensors reply with an InfoSlave and an InfoFree message respectively. These replies contain key information to perform the PUSH & PULL algorithm, and in particular: all three types of replies contain the ID and geographic coordinates of the replying sensors, while the InfoSnapped and InfoSlave messages contain additional information. In particular, the InfoSnapped message includes also the virtual cardinality of the replying snapped sensors while the InfoSlave message includes the energy level of the replying slave sensors.

Thanks to the execution of the neighbor discovery phase, a snapped sensor p is informed regarding the presence of vacant positions, i.e. knows the composition of $VP(p)$.

2) *Snap into position*: A snapped sensor p selects the closest sensor in $L(p)$ to each uncovered position and sends it a SIP (Snap Into Position) message. This message contains the target position of the correspondent snap action, and the ID of the selected sensor.

If a sensor receives a SIP, and is available to fill the vacant position, it replies with an AckSIP message. This message contains the ID of the sensor that received the SIP, necessary for p to discriminate among the several sensors to which it sent SIP messages. If a sensor receives a SIP when it is not available to fill the vacant position (e.g it has already been contacted by another sensor), it does not reply to the SIP message of p and lets the AckSIP timeout expire. This way p will be capable to select a new sensor to snap in such still vacant position.

After the transmission of the SIP messages and the reception of the related AckSIP, p updates its local information, i.e. the number of free sensors located within its transmission range and its *virtual cardinality*. This way it keeps into account

Message name	Message fields
IAS	ID, coordinates, starter timestamp
InfoSnapped	ID, coordinates, virtual cardinality
InfoSlave	ID, coordinates, energy level
InfoFree	ID, coordinates
SIP	ID, receiver ID, target position coordinates
AckSIP	ID, receive ID
ClaimPosition	ID, coordinates, timestamp
PositionTaken	ID, coordinates
InfoStopped	ID, coordinates
IAYS	ID, receiver ID
CardinalityInfo	ID, virtual cardinality
Offer	ID, receiver ID, virtual cardinality, transaction ID
AckOffer	ID, receiver ID
MoveTo	ID, receiver ID, destination coordinates, destination snapped sensor ID, transaction ID
InfoArrived	ID, receiver ID, transaction ID, energy level
HoleInfo	ID, hop counter, order value, hole coordinates, timeout
Subst	ID, receiver ID, energy level
AckSubst	ID, receiver ID
SubstArrival	ID, receiver ID
ProfilePacket	ID, receiver ID, order value, priority queue, neighborhood information
MoveToSubst	ID, receiver ID, order value, priority queue, neighborhood information
Retirement	ID, hole coordinates

TABLE I
SUMMARY OF P&P MESSAGES

the departure of some sensors from either its transmission range or its hexagon.

In order to update the information related to the snapped neighbors, p waits for the reception of the corresponding IAS messages, to be sure that position conflicts are solved (see IV-C3). No messages are involved in this phase that consists in a mere calculation based on locally available information.

Let p be the sensor that is performing the snap action and let q be the one to which p sent a SIP message for the position x . Five cases may occur, described as follows.

- 1) Sensor p receives both the AckSIP and the IAS message from q . This means that the snap action performed by p was successful, therefore p can update the local information regarding the snapped neighbor q .
- 2) Sensor p receives the AckSIP from q acknowledging its availability to fill position x , but a conflict occurs solved in favor of another sensor r , which reaches position x before sensor q . Hence p receives an AckSIP from q and a IAS from r for the same position x . Thus p can update the local information regarding the snapped neighbor r .
- 3) Sensor p receives the AckSIP from q acknowledging its availability to fill position x , but a failure occurred and the IAS timeout expires. If p detects the availability of another sensor in $L(p)$ that can be snapped to position x , it retries the snap action. If such sensor is not available, p starts the pull action.
- 4) Sensor p does not receive the AckSIP from q , but receives a IAS message for position x from another sensor r , before the expiration of the AckSIP timeout. Sensor p can update the local information regarding the snapped neighbor r .
- 5) Sensor p does not receive the AckSIP from q nor the IAS from any other sensor within the AckSIP timeout. If p detects the availability of another sensor in $L(p)$ that can be snapped

Fig. 1. Snapped sensor behavior

to position x , it retries the snap action. If such sensor is not available, p starts the pull action.

The behavior of a snapped sensor p can be sketched as in Figure 1. It dwells in the snap phase until there are available sensors in $L(p)$ and vacant positions in the adjacent hexagons. If there are vacant positions and no sensors in $L(p)$, sensor p gives start to the pull action to attract new sensors from overcrowded areas. If otherwise there are available sensors in $L(p)$ and no vacant positions, p starts the push action to uniform the redundant sensor distribution.

C. Behavior of the sensors being snapped

- 1) *Sensor localization*: A free sensor q which receives a IAS message, coming from a snapped sensor p , replies with either an InfoFree or an InfoSlave message depending on its position with respect to p . If q is located outside the

Fig. 2. A typical scenario of snap position conflict between two sensors

hexagon of p , it remains in the free state and replies to p with an **InfoFree** message. If instead q is located inside the hexagon of p , it switches its state to slave and replies to p with an **InfoSlave** message. In both cases q becomes part of the set $L(p)$, that is the set of sensors that p can snap to its adjacent vacant positions. Notice that if q is a slave, there is only one snapped sensor p such that $q \in L(p)$, thus slaves belonging to already snapped sensors do not reply to the IAS message of p . If instead q is a free sensor, it may belong to several sets $L(\cdot)$, for different snapped sensors located in radio proximity from q itself.

2) *Snap into position*: Sensor q , be it free or slave, at a certain time, may receive a **SIP** message coming from a snapped sensor. Slaves reply only to **SIP** messages coming from their related snapped sensor, while free sensors only reply to the first **SIP** message they receive and ignore subsequent ones.

After sending the **AckSIP** reply, sensor q travels towards the snapping destination until it reaches a distance d from it. Distance d is set small enough to guarantee the radio connectivity within the circular disk of radius d and the inclusion of such disk into the hexagonal tile. Therefore $d \leq \sqrt{3}R_s/2$.

At this point sensor q stops and broadcasts a **ClaimPosition** message containing a timestamp and waits for the expiration of a timeout to evaluate if other sensors are trying to snap in the same position and in case to resolve the related contention. At the timeout expiration, if no conflicts occurred or if a conflict was solved in its favor, q switches its state to snapped, sends a **PositionTaken** message and proceeds towards the destination. After being

successfully snapped, sensor q starts its own snap activity.

3) *Resolution of snap position contention*: Three events may occur when one or more sensors are engaged in a conflict with sensor q due to the contention for the same snap position:

- 1) sensor q receives a **ClaimPosition** or a **PositionTaken** before reaching distance d from the destination,
- 2) sensor q receives a **ClaimPosition** after the arrival at distance d from the destination and before the expiration of the related timeout,
- 3) sensor q receives a **PositionTaken** as a response to its **ClaimPosition**. This case may happen if q started travelling toward the destination when it was too far to perceive the previous **ClaimPosition** and **PositionTaken** messages.

In the first case, q stops moving and sends an **InfoStopped** message, to advertise its new position to the neighborhood, and starts a timeout. Snapped sensors receiving the **InfoStopped** message, verify if the sender is inside their hexagons and in this case reply with a **IAYS** message (I Am Your Snapped), containing the sender and the receiver ID. If the stopped sensor receives a **IAYS** reply within the timeout, it sets its status to slave. Otherwise, if the timeout expires, it sets its status to free, not belonging to any hexagon.

In the second case, sensor q compares its timestamp with the one included in the **ClaimPosition** message. The sensor with lower timestamp wins the competition for the destination and proceeds its travel, sending a **PositionTaken** message, while the other sensor waits for the arrival of the IAS message of the new snapped sensor to switch its status to slave.

In the third case, sensor q sets its state to slave of the newly snapped sensor. Notice that this timestamp based conflict is designed to avoid redundant replies to **ClaimPosition** messages.

Figure 2 shows a typical conflict resolution scenario, where two sensors r and q receive a **SIP** message for the same position x from two different snapped sensors. Both r and q start travelling towards the destination x . Sensor q reaches distance d from the destination before sensor r , and sends a **ClaimPosition** message, with its timestamp. Sensor r receives such message while travelling, and consequently stops because the contention for position x was won by sensor q . Sensor r sends an **InfoStopped** message to alert its neighborhood of its new position and starts a timeout. In the case depicted in Figure 2, r stops inside the hexagon centered in position x . For this reason, no snapped sensor replies to the **InfoStopped** message, thus after the timeout expiration, sensor r switches its status to free. After the expiration of the contention timeout, sensor q broadcasts a **PositionTaken** message and switches to the snap status while definitely travelling to position x . When q reaches position x , it starts a neighbor discovery by sending a **IAS** message, in consequence of which, r switches its status to slave.

a complete role exchange and starts travelling towards the destination.

If sensor r does not receive an **AckSubst** message within the substitution timeout, it continues its travel towards the destination.

Slave and snapped sensor substitutions may also occur at the beginning of the slave travel. In this case the substitution is started by the snapped sensor itself which already has all the available information to evaluate the opportunity to perform the role exchange. Under these circumstances, the snapped sensor p sends a **MoveToSubst** message containing the profile information necessary to perform the substitution. As soon as sensor r arrives in proximity to the snap position held by p , it sends the **SubstArrival** message described before, after which p starts travelling towards the destination.

D. An example

Figure 3 depicts a typical scenario of the push activity. The snapped sensor q broadcasts its virtual cardinality with a **CardinalityInfo** message. The snapped sensors p and z receive this message and verify the Moving Condition with the updated information received from q . As both p and z satisfy the condition, they send an **Offer** message to q . Notice that the **Offer** message always contains an updated value of the virtual cardinality of the sender. Since each node can offer at most one sensor at a time the virtual cardinality does not change until the offer timeout expires, or the receiver replies with an **AckOffer** message. Sensor q receives the **Offer** message from p before the one sent from sensor z . It verifies the validity of the Moving Condition with the updated virtual cardinality of p , received in the **Offer** message. As the Moving Condition is still satisfied, q replies with an **AckOffer** message, incrementing its virtual cardinality and broadcasting a **CardinalityInfo** message.

When node q receives the **Offer** message from z it verifies the Moving Condition again. Note that z sent this message on the basis of an old value of the virtual cardinality of q . Thus q finds that, as a consequence of the transaction just concluded with sensor p , the Moving Condition is unsatisfied with respect to sensor z , and consequently it does not reply to the offerer. Sensor z waits until the expiration of the offer timeout, after which it is able to be engaged in other push actions.

Sensor p receives an **AckOffer** message from q , thus it selects r within its slaves, and send it a **MoveTo** message. Sensor r moves towards the hexagon of q , and sends an **InfoArrived** message as soon as it arrives. Sensor p sends a **CardinalityInfo** message containing the decreased value of its virtual cardinality.

VI. P&P: PULL ACTIVITY

In the present section we distinguish three possible roles of sensors involved in the pull activity.

A first role is the one of the sensor detecting a coverage hole in a neighbor location. This is the starter of the pull activity, which alters its *ord* value to enable push actions from nearby hexagons and sends related trigger notification messages.

The second role is the one of the neighbor snapped sensors which receive the trigger notification messages while not having available slaves to send. These sensors act as forwarder of the trigger messages in order to reach hexagons with redundant slaves that can be moved (pushed) to fill the coverage holes.

The third role is performed by the snapped sensors which receive a trigger message when having available slaves to push. These sensors are informed of the changed *ord* value of the neighbor snapped sensors, and can contribute to fill the coverage holes by pushing the available slaves in the proper direction.

Notice that multiple trigger notification messages may reach the same sensor while performing any of the three listed roles. Such messages are queued and processed with a priority inversely proportional to the distance from the coverage hole.

A. Behavior of sensors detecting coverage holes

A snapped sensor p , located in proximity of some vacant positions (i.e. $VP(p) \neq \emptyset$), terminates the snap activity when no more sensors are available in $L(p)$. To give start to the pull activity, sensor p verifies if there is the possibility to attract sensors from its snapped neighbors. To this purpose, sensor p checks the validity of the Moving Condition with respect to all its snapped neighbors.

If p can not continue the snap activity nor receive any sensor from its snapped neighbors, it starts the pull activity. To this purpose sensor p sets its *ord* value to zero, and advertises this change by broadcasting a **HoleInfo** message containing its ID, a hop counter h , its updated *ord* value, the vacant position coordinates, and a timeout t_{out} which depends on the value of h (notice that this information is redundant but is introduced to increase the algorithm efficiency). By modifying its *ord* value, sensor p alters the current situation with respect to the Moving Condition, enabling a new push activity from neighbor hexagons.

The hop counter h represents the forwarding horizon of the **HoleInfo** message, that is the distance to be traversed by this message, expressed in number of hexagons. Initially h is set to zero, thus the snapped sensors receiving a **HoleInfo** message only update their information about the sender *ord* value and do not forward this message. If no new slave reaches $Hex(p)$ within the given timeout t_{out} , sensor p increases h and broadcasts a new **HoleInfo** message.

The timeout t_{out} is calculated on the basis of the hop counter h as the time necessary for a sensor located $(h + 1)$ hops apart to reach $Hex(p)$, that is $t_{out} = (h + 1) \cdot 2R_s/v$, where v is the sensor speed.

Figure 4 illustrates the pull action performed by sensor p as described above.

B. Behavior of trigger forwarder sensors

When a sensor p receives a **HoleInfo** message and has not any slave to push toward the coverage hole, it participates in the pull activity by forwarding this message when necessary. In particular, it discards **HoleInfo** messages related to holes whose presence was already triggered by a snapped sensor q ,

Fig. 4. Behavior of a sensor detecting a coverage hole

unless they contribute additional information. Indeed sensor p evaluates new messages regarding a coverage hole previously advertised by sensor q only if they come from:

- 1) snapped sensors with ord value lower than $ord(p)$ or
- 2) snapped sensors with the same ord as p and hop counter h which is higher than the forwarding horizon issued by sensor q .

Case 1) happens when a new snapped sensor r detects the same coverage hole advertised by q , but the distance between p and r is lower than the distance between p and q . Case 2) happens when sensor q issues a new hole trigger demanding a forwarding horizon extension.

When processing **HoleInfo** messages, sensor p alters its status information, and in particular sets its order value equal to the adjacent sender order value increased by 1. Sensor p then forwards the trigger to its adjacent snapped sensors only if $h > 0$. Such forwarded trigger message contains the updated status information of p and a hop counter decreased by 1.

If sensor p receives several **HoleInfo** messages concurrently, it inserts them in a pre-emptive priority queue, where each message is treated with a priority that is inversely proportional to the distance from the coverage hole.

Sensor p sets back its ord to the original value as soon as the timeout of the **HoleInfo** message expires. This is necessary to stop the pull action after the coverage of the detected hole.

C. Behavior of sensors pushing redundant slaves

When a sensor p receives a **HoleInfo** message and finds an available slave to push towards the coverage hole, it updates the local information regarding its neighborhood. Thanks to the sequence of order value alteration, p finds a valid Moving Condition with respect to the direction of the coverage hole and properly starts a push activity.

Fig. 5. A typical scenario of the pull activity

D. An example

Figure 5 shows a typical scenario of the pull activity. The snapped sensor p detects a coverage hole in an adjacent position. Since p has no slaves in its hexagon and the Moving Condition with respect to its neighbors is unsatisfied, it starts the pull activity by setting its ord value to zero and broadcasting a **HoleInfo** message with null hop counter. Since sensor q does not have any slave to push toward p , at the expiration of the timeout, sensor p broadcasts another **HoleInfo** message increasing the previous hop counter. Sensor q evaluates the hop counter of the **HoleInfo** message it received from p and sets its own ord value to 1. Sensor q then forwards the trigger by broadcasting a **HoleInfo** message with decreased hop counter. Once again the timeout set by p expires because not even sensor z has any slave to push, thus the procedure is repeated until the trigger, represented by the **HoleInfo** message, reaches sensor r which instead has an available slave s to push as it does according to the same procedure described in section V.

VII. P&P: MERGE ACTIVITY

The fact that many sensors act as starters implies the generation of several tiling portions with different orientations. The aim of the **PUSH & PULL** algorithm is to cover the AoI with a unique regular tiling thus minimizing overlaps of the sensing disks and enabling a complete and uniform coverage.

Hence, the algorithm provides a merge mechanism to be executed whenever a sensor p receives a neighbor discovery message (IAS) from a snapped sensor q belonging to another tiling portion.

In this case, sensor p chooses to join the oldest grid portion (it discriminates this situation by evaluating the timestamp of the starter action, attached to any IAS message).

Notice that the detection of the sole neighbor discovery messages is sufficient to ignite the tiling merge activity because such messages are sent after any tiling expansion and, if two tiling portions come in radio proximity to each other, at least one of them is increasing its extension. In the following, we call G_{old} and G_{new} the tiling portions with lower and higher timestamp, respectively. We distinguish three possible cases.

1) Sensor p belongs to G_{new} and receives a IAS message from q belonging to G_{old} . If sensor p is a slave, it switches its state to free or to slave of the sensor q depending on their mutual distance. Sensor p proactively communicates its new state to its neighborhood by sending either an InfoFree or an InfoSlave message. From now on p honors only messages from G_{old} and ignores those from G_{new} .

This proactive communication of the new state of p is needed to advertise the presence of G_{new} when there is no message activity within G_{new} that is perceivable by the sensors in G_{old} . This way, the snapped sensor which p belonged to can properly update its slave set.

If p is instead a snapped sensor, it can not immediately switch to its new state because of its leading role inside G_{new} (e.g. it leads the slave sensors in $S(p)$ and performs push and pull activities). Hence p temporarily assumes a hybrid role: it advertises itself as free/slave to the nodes of G_{old} with an InfoFree/InfoSlave message and, at the same time, keeps on behaving as snapped node in G_{new} until it receives a movement command (SIP or MoveTo message) coming from G_{old} .

If p received a SIP or a MoveTo command, p moves to the new snap position electing one of its slave in G_{new} as a substitute with a MoveToSubst message. The selected slave should reply with a SubstArrival upon arrival to the snap position, within a given timeout. If this timeout expires before the reception of such SubstArrival message, p selects a new slave to snap. The process goes on until no more slaves are available. In this case p ceases its snapped role inside G_{new} advertising its departure to its neighbors in G_{new} , broadcasting a Retirement message. Upon reception of a Retirement message the snapped neighbors that were located in positions adjacent to the one that p just freed, keep into account the new vacant position starting new snap activities. If otherwise, p receives a SubstArrival on time, it ceases its snapped role in G_{new} and honors the commands issued by the snapped node in G_{old} .

2) Sensor p belongs to G_{old} and receives a IAS message from q belonging to G_{new} : if p is a slave it ignores all messages from G_{new} . If p is snapped, it performs a neighbor discovery sending a IAS message, ignores all messages coming from G_{new} , apart from the neighbor discovery replies, and honors

Fig. 6. Coverage of an irregular AoI

Fig. 7. Deployment with random initial distribution

only messages from G_{old} . Observe that the neighbor discovery is necessary to ignite the merge mechanism and allows each snapped sensor in G_{old} to collect complete information on nearby sensors that previously belonged to G_{new} .

3) Sensor p is free: sensor p honors only messages from G_{old} and ignores those from G_{new} .

VIII. SIMULATION RESULTS

In order to evaluate the performance of the P&P protocol we developed a simulator on the basis of the wireless module of the OPNET modeler software [11].

The experimental activity required the definition of some setup parameters: $R_{tx} = 11$ m, $R_s = 5$ m and the sensor speed is 1 m/sec.

We show some examples of final deployments provided by the proposed protocol. Figure 6 gives a synthetic representation of how the sensor deployment evolves under P&P when starting with an initial configuration where 150 sensors are sent from a high density region. The AoI has a complex shape in which a narrow connects two square regions $40 \text{ m} \times 40 \text{ m}$.

In the following we also show three other deployment examples obtained with different initial sensor deployments over the same AoI, that is a square $80 \text{ m} \times 80 \text{ m}$.

In the first example, the initial deployment evidences a random distribution of sensors over the AoI as depicted in Figure 7(a). With such initial configuration the deployment obtained by P&P evolves through the intermediate stages (b) and (c), achieving the final deployment shown in figure (d).

Fig. 8. Deployment with high density initial distribution at the boundaries of the AoI

Fig. 9. Deployment with high density initial distribution at the center of the AoI

In the second example the initial deployment consists of a high density region at the boundaries of the AoI as depicted in Figure 8(a). With such initial configuration P&P achieves the final deployment detailed in (d) evolving as in (b) and (c).

In the third example, the initial deployment consists of high density region at the center of the AoI as depicted in Figure 9(a). With such initial configuration, the deployment obtained by P&P evolves through the configurations shown in (b) and (c), reaching the final deployment given in (d).

Fig. 10. Term. and coverage time

Fig. 12. Snap conflicts

Fig. 11. Nr of message exchanges

Fig. 13. Push conflicts

We introduce some experiments conducted starting from the configuration depicted in figure 9(a), by varying the number of sensors. Results are average values calculated over 30 simulation runs. Figure 10 shows the coverage and termination

time of the protocol execution. By coordinating distributed decisions and solving local conflicts, the P&P protocol guarantees the termination of the PUSH & PULL algorithm in moderate time. Notice that after the coverage completion, the PUSH & PULL algorithm keeps on regulating some movements to uniform the redundant sensor density. The termination time evidences the capability of the P&P protocol to reach a final stable configuration, where neither movements nor message exchanges are performed.

The average number of message exchanges, shown in Figure 11, evidences a good scalability of the P&P protocol. Indeed this number remains stable even when the number of sensors increases significantly.

Figure 12 represents the number of conflicting snap actions, described in section IV, averaged over the number of snap positions. The asynchronous behavior of P&P guarantees the resolution of the few position conflicts that arise as a consequence of the distributed execution of the algorithm PUSH & PULL. Although growing with the number of available sensors, the average number of snap conflicts remains significantly smaller than 1, meaning that, in the considered scenarios, no more than one conflict happens per snap position.

A push conflict happens when a push offer made by one sensor becomes obsolete in consequence to push actions performed by others. Despite the distributed execution of the P&P protocol, the average number of push conflicts per slave sensor is stable with a growing number of sensors, as shown in Figure 13.

IX. CONCLUSIONS

In this paper we introduce P&P, a communication protocol that permits a correct and efficient coordination of sensor movements in agreement with the PUSH & PULL algorithm.

Unlike previous works which introduce deployment algorithms without formalizing the related protocol, we address the realistic applicability of this approach. Indeed we deeply investigate and propose protocol solutions to the possible conflicts that may arise when asynchronous local decisions are to be coordinated.

Simulation results show the performance of our protocol under a range of operative settings, including conflict situations, irregularly shaped target areas, and node failures. These results evidence the protocol capabilities to fulfill the algorithm requirements and in particular termination, completeness and stability of the final coverage.
